## ABSTRACT

Differential evolution (DE) is a simple yet powerful evolutionary algorithm that has been used to solve various complex optimization problems in numerous engineering fields. However, DE has some problems, such as premature convergence and sensitivity to parameter settings. To improve the performance of DE and extend its application, an adaptive differential evolution with the Lagrange interpolation argument algorithm (ADELI) is proposed in this paper. To accelerate the convergence speed of DE, a local search with Lagrange interpolation (LSLI) is introduced into DE. LSLI performs a local search in the neighborhood of the best individual in the current generation to enhance the exploitation capability of DE. Meanwhile, an adaptive argument strategy is presented to adaptively determine whether to use LSLI in terms of its performance in the previous generation, which can balance the global exploration capability and the local exploitation capability of ADELI. To verify the feasibility and effectiveness of ADELI, 30 test functions in the CEC 2014 benchmark sets with different dimensions were simulated. Moreover, a path synthesis problem was also optimized. The results demonstrated that ADELI considerably outperforms other EAs in most functions and obtains the most accurate solution among the compared algorithms in the application of path generation.

## 1. Introduction

Recently, evolutionary algorithms (EAs) have been widely applied to solve optimization problems in various fields such as engineering and science. In contrast to conventional methods based on mathematical programming or formal logics, EAs are found to be more powerful and flexible [43]. However, current EAs may have problems such as the computation becoming trapped in local optima and a slow convergence speed in solving complex optimization problems, such as nonlinear and nondifferentiable problems [47]. There is a need to develop more effective and efficient EAs. To discourage premature convergence and improve the performance of EAs, increasingly more researchers have been devoted to modifying existing EAs or to developing new EAs based on swarm intelligence and genetic evolution. Numerous EAs have been proposed and successfully applied in science and engineering fields. The commonly used EAs include the genetic algorithm (GA) [22], ant colony optimization (ACO) [12], particle swarm optimization (PSO) [24], DE [37], the quantum-inspired evolutionary algorithm (QEA) [21], harmony search (HS) [46], cuckoo search (CS) [44], teach-learning-based optimization (TLBO) [32], krill herd (KH) [18], the backtracking search optimization algorithm (BSA) [8], etc.

In stochastic algorithms (i.e., meta-heuristics), most of them are population-based search algorithms. ACO, inspired by the foraging behavior of ants, has been proposed to solve combinatorial optimization problems [12]. To tackle continuous optimization problems, an extension of ACO for continuous domains (ACOR) was proposed [36]. QEA adopts the concept and principles of quantum computing, and it uses a Q-gate as a variation operator to lead the population toward convergence [21]. To improve the performance of the quantum algorithm, an adaptive quantum inspired genetic algorithm (aQIGA) was proposed in [5]. It uses adaptive control parameters to guide the distribution toward the better regions.

PSO has attracted much attention due to its ease of implementation and intelligent search capabilities. It is inspired by the social foraging behaviors of bird flocking and fish schooling. Unlike other EAs, PSO has two prominent characteristics. First, it does not use the law of survival of the fittest, and all particles are retained as members of the population through the evolutionary process. Second, it has no genetic operators such as mutation or crossover [17]. However, PSO is susceptible to falling into a local optimum solution in complex optimization problems. To improve PSO's performance, numerous significant variants of PSO have been proposed, which can be divided into three main categories: first, the parameters are introduced and modified, such as the inertia weight [33] and the linearly decreasing inertia weight [34]; second, an introduction of new topology structures or techniques is proposed, including the dynamic neighborhood learning strategy [27], human learning strategies [38], and simulated annealing [35]; and third, hybridization with other algorithms is adopted, such as HS [46], DE [14], and GA [19]. Liang et al. [26] presented a comprehensive learning PSO (CLPSO). Unlike PSO learning from the global best experience among the swarm, CLPSO learns from other particles' historical best experience. It enlarges the swarm's diversity to avoid premature convergence to improve PSO's performance on multimodal problems.

All the above mentioned EAs are nature-inspired population-based algorithms; however, they have some drawbacks, such as sensitivity to parameter settings. As the selection of parameters can significantly influence the performance of the algorithm, TLBO does not use algorithm-specific parameters [32]. Enhancement is accomplished either by introducing an elitism concept for TLBO (ETLBO) [31], or by utilizing a dynamic group strategy in TLBO (DGSTLBO) [47]. In DGSTLBO, learners can be regrouped dynamically and exchange information with each other. It protects the diversity of the population and avoids falling into the local optima to enhance TLBO's performance in addressing complex problems with multiple local optima.

BSA is a population-based stochastic search method with genetic operators [8]. It does not require algorithm-specific parameters, enabling an easy implementation and providing the flexibility to handle different complex optimization problems [6]. Duan and Luo [13] proposed an adaptive BSA with a varied mutation and crossover rate to optimize the mass and dimension of induction magnetometers. Wang et al. [41] hybridized BSA with DE to enhance the convergence of BSA. Chen et al. [7] developed the learning BSA (LBSA) by incorporating TLBO's learning idea in BSA and modifying the mutation process to improve the diversity of the population and the exploration capability of algorithm.

DE has a simple algorithmic structure, and it is a highly powerful and versatile evolutionary optimizer for complex search spaces. Hence, it is very popular and has been widely applied to address optimization problems in diverse fields [9]. Although DE shows great potential to solve many optimization problems, DE, similar to other EAs, also has some drawbacks, such as sensitivity to parameters, selection of mutation and crossover strategies [8], level of difficulty for solving functions that are not linearly separable [10], etc.

To enhance DE's performance, improvement studies of DE are conducted, which can be divided into two groups. The first group aims to modify the structures of DE. Brest et al. [3] proposed a novel approach to self-adaptively determine the control parameters for DE (jDE). When solving different computational problems, this method will adaptively adjust the control parameters of DE to obtain a better solution. The self-adaptive method is very efficient and easy to implement. Later, Qin et al. [30] presented a self-adaptive DE (SaDE), in which the mutation strategies and control parameters are self-adaptively updated in terms of previous experiences. Zhang and Sanderson [45] proposed a new DE variant that incorporates parameter adaptation and a new mutation strategy into DE to improve its performance and increase the convergence speed. Guo and Yang [20] proposed an eigenvector-based crossover operator to enhance DE's performance, which can also be applied to other DE versions. Ahmadianfar et al. [1] proposed the enhanced DE by utilizing two new mutation operators to balance exploration and exploitation capabilities, and applied it to optimize multi-reservoir operation problems.

The second group of improvement studies of DE focuses on integrating an extra component into DE. In this group, the modified versions of DE can be subdivided into two classes. In the first class, some studies consider a hybrid evolutionary framework of DE with other meta-heuristics, such as PSO [14], GA [40], HS [11] and so on. In the second class, in order to enhance DE's local exploitation capability, some limited studies are aimed at combining DE with local search methods. A crossover based on a local search scheme, the fittest individual refinement [28], was used for exploration around the best individual to help accelerate DE on high-dimensional functions. Afterwards, Noman and Iba [29] combined DE with an adaptive local search technique. It uses a hill-climbing heuristic to adaptively adjust the search length, which has been proven to be very promising. Tirronen et al. [39] presented a hybridization of DE with a scale factor local search algorithm to guarantee a high quality solution. Xie et al. [42] presented a diversity-maintained gradient-based DE (DMGBDE), which embeds a gradient local search method into DE to improve its local exploitation abilities, and introduced a diversity-maintained mutation operator to avoid premature convergence.

As mentioned above, DE has become popular due to its ease of implementation and has shown a promising performance on many global optimization problems. Both the adaptive DE with the parameter control and the hybridization of DE with a local search technique have shown faster and more reliable convergence performance than the basic DE.

To improve DE's performance on global optimization problems, we propose a novel algorithm, ADELI, which is based on DE by incorporating an adaptive local search scheme with Lagrange interpolation. First, Lagrange interpolation is introduced

into DE with a self-adaptive control parameter, and it performs local search in the neighborhood of the best individual. This local search scheme is used to enhance the exploitation capability to accelerate the convergence speed of DE. Second, an adaptive argument strategy is presented to adaptively determine whether to use Lagrange interpolation for the local search in one generation. This mechanism is used to improve the efficiency of ADEL.

In this paper, 30 benchmark functions from the CEC 2014 sets and an application of path generation are used to examine the feasibility of ADEL. The results are compared with those generated by ten widely used algorithms including ACOR [36], QEA [21], aQIGA [5], CLPSO [26], jDE [3], SaDE [30], ETLBO [31], DGSTLBO [47], BSA [8], and LBSA [7].

The rest of this paper is organized as follows. Section 2 briefly describes the procedure of the basic DE. Section 3 introduces Lagrange interpolation. The proposed ADEL is elaborated in Section 4, with detailed explanations on local search with Lagrange interpolation and the adaptive argument strategy. Numerical experiments are conducted in Section 5, and the application for path generation problems is optimized in Section 6. Finally, conclusions are summarized in Section 7.

## 2. DE

DE is a highly powerful and efficient evolutionary algorithm for solving optimization problems; it contains four operations: initialization, mutation, crossover, and selection, which are described below. Further details can be found in [37].

### 2.1. Initialization

The population of DE consists of  $N$  numbers of  $D$ -dimensional parameter vectors, i.e.,  $x_i = [x_{i,1}, x_{i,2}, \dots, x_{i,D}]$ ,  $i = 1, 2, \dots, N$ . The parameters of the  $i$ th individual of the initial population are generated according to:

$$x_{i,j} = (x_j^{\text{up}} - x_j^{\text{low}}) * \text{rand}(0, 1) + x_j^{\text{low}}, j = 1, \dots, D \quad (1)$$

where  $x_j^{\text{up}}$  and  $x_j^{\text{low}}$  are the upper and lower boundaries of individuals in the  $j$ th-dimensional search space, respectively, and  $\text{rand}(0, 1)$  is a uniformly distributed random number in the range  $(0, 1)$ .

### 2.2. Mutation

After the initialization, the mutation procedure is employed. For each target vector  $x_i$ ,  $i = 1, 2, \dots, N$ , a mutant vector  $v_i^{\text{child}}$  is generated by a mutation procedure. The mutation strategy is given as follows:

$$v_i^{\text{child}} = x_{ra} + F(x_{rb} - x_{rc}) \quad (2)$$

where  $ra$ ,  $rb$  and  $rc$  are randomly chosen from  $\{1, 2, \dots, N\}$ , which are different from each other.  $F$  is a user-specified scaling factor in the range  $(0, 2)$ .

If a mutation vector exceeds the upper and lower boundaries, it will be initialized by using Eq. (1).

### 2.3. Crossover

To increase the population diversity, the crossover operation is implemented to yield a trial vector  $u_i^{\text{child}} = \{u_{i,1}^{\text{child}}, \dots, u_{i,D}^{\text{child}}\}$ . The crossover scheme of DE can be mathematically written as follows:

$$u_{i,j}^{\text{child}} = \begin{cases} v_{i,j}^{\text{child}} & \text{if } (\text{rand}(0, 1) < CR) \text{ or } (j = j_{\text{rand}}) \\ x_{i,j} & \text{otherwise} \end{cases} \quad (3)$$

$j = 1, 2, \dots, D$

where  $j_{\text{rand}}$  is randomly chosen from  $\{1, 2, \dots, D\}$  to ensure that  $u_i^{\text{child}}$  inherits at least one element from  $v_i^{\text{child}}$ , and  $CR$  is the crossover rate defined by users within the range of  $[0, 1]$ .

### 2.4. Selection

After crossover, the trial vector  $u_i^{\text{child}}$  is calculated by the objective function. Then, the greedy selection mechanism is implemented to yield the population that can survive in the next generation in terms of the fitness value. If the fitness value of each trial vector  $u_i^{\text{child}}$  is better than the corresponding target vector  $x_i$ , then the trial vector  $u_i^{\text{child}}$  will survive into the next generation; otherwise, the target vector  $x_i$  will survive. The selection procedure can be mathematically expressed as Eq. (4).

$$x_i^{\text{child}} = \begin{cases} u_i^{\text{child}} & \text{if } (f(u_i^{\text{child}}) < f(x_i)) \\ x_i & \text{otherwise} \end{cases} \quad (4)$$

The pseudocode for DE is given in Algorithm 1.

Fig. 1. Solutions of Lagrange interpolation in the  $j$ -th-dimensional space for  $I \neq 0$ .

### 3. Lagrange interpolation

Lagrange interpolation is a method to obtain a polynomial which can pass through all the given points accurately, rather than approximately. In the  $j$  th-dimensional search space, the Lagrange interpolation polynomial  $P(x_j)$  of degree  $d$  passes through  $d + 1$  different given points  $(x_j^0, f(x^0))$ ,  $(x_j^1, f(x^1))$ , ...,  $(x_j^d, f(x^d))$ ,  $j = 1, \dots, D$ , where  $x_j^k$  is the  $j$  th parameter in vector  $\mathbf{x}^k = \{x_1^k, x_2^k, \dots, x_D^k\}$ ,  $k = 0, \dots, d$ , and  $f(\mathbf{x}^k)$  is the corresponding fitness value of  $\mathbf{x}^k$ , i.e.,  $f(\mathbf{x}^k) = f([x_1^k, x_2^k, \dots, x_D^k])$ . It satisfies  $P(x_j^k) = f(x^k)$ , as shown in Eq. (5):

$$P(x_j) = \sum_{k=0}^d \left[ \left( \prod_{\substack{m=0 \\ m \neq k}}^d \frac{x_j - x_j^m}{x_j^k - x_j^m} \right) f(x^k) \right], j = 1, \dots, D \quad (5)$$

$P(x_j)$  is the interpolation polynomial of fitness  $f(x)$ . When degree  $d = 2$ , i.e.,  $P(x_j)$  passes through three points  $(x_j^0, f(x^0))$ ,  $(x_j^1, f(x^1))$  and  $(x_j^2, f(x^2))$ , it can be written as Eq. (6):

$$P(x_j) = \frac{(x_j - x_j^1)(x_j - x_j^2)}{(x_j^0 - x_j^1)(x_j^0 - x_j^2)} f(x^0) + \frac{(x_j - x_j^0)(x_j - x_j^2)}{(x_j^1 - x_j^0)(x_j^1 - x_j^2)} f(x^1) + \frac{(x_j - x_j^0)(x_j - x_j^1)}{(x_j^2 - x_j^0)(x_j^2 - x_j^1)} f(x^2) \quad (6)$$

$j = 1, \dots, D$

Eq. (6) can be rewritten as:

$$P(x_j) = a(x_j)^2 + bx_j + c, j = 1, \dots, D \quad (7)$$

where:

$$a = \frac{1}{I} [(x_j^2 - x_j^1)f(x^0) + (x_j^0 - x_j^2)f(x^1) + (x_j^1 - x_j^0)f(x^2)] \quad (8)$$

$$b = \frac{1}{I} \left[ ((x_j^1)^2 - (x_j^2)^2)f(x^0) + ((x_j^2)^2 - (x_j^0)^2)f(x^1) + ((x_j^0)^2 - (x_j^1)^2)f(x^2) \right] \quad (9)$$

$$c = \frac{1}{I} [(x_j^2 - x_j^1)x_j^1x_j^2f(x^0) + (x_j^0 - x_j^2)x_j^0x_j^2f(x^1) + (x_j^1 - x_j^0)x_j^0x_j^1f(x^2)] \quad (10)$$

$$I = (x_j^0 - x_j^1)(x_j^1 - x_j^2)(x_j^2 - x_j^0) \quad (11)$$

The value of  $I$  decides the solution of the optimum position  $x_j^3$ . When  $I \neq 0$ , i.e., three points are distinct, as shown in Fig. 1, there are four cases:

If  $a > 0$ , the parabola passes through three points and opens upwards; the minimal point of the parabola is the solution, i.e.,  $x_j^3 = -b/2a$ .

If  $a = 0, b = 0$ , three points arrange in a horizontal line, i.e.,  $f(x^0) = f(x^1) = f(x^2)$ ;  $x_j^3$  can be randomly chosen between three points.

If  $a = 0, b \neq 0$ , three points arrange in a non-horizontal straight line;  $x_j^3$  can be randomly chosen at the neighbor of the minimum point among three points and can search along the decreasing direction of the line.

If  $a < 0$ , the parabola opens downwards and there is no minimal point;  $x_j^3$  can be solved as the case of  $a = 0, b \neq 0$ .

The solution of  $x_j^3$  can be summarized as Eq. (12):

$$x_j^3 = \begin{cases} -\frac{b}{2a} & \text{if } a > 0 \\ \frac{1}{2}(x_j^1 + x_j^2) + (\text{rand} - 0.5)(x_j^1 - x_j^2) & \text{else if } (a = 0) \text{ and } (b = 0) \\ x_j^{\min} + \text{rand} * c_3 * (x_j^{\min} - x_j^{\text{mid}}) + \text{rand} * c_4 * (x_j^{\min} - x_j^{\max}) & \text{otherwise} \end{cases} \quad \begin{matrix} \text{(a)} \\ \text{(b)} \\ \text{(c)} \end{matrix} \quad (12)$$

$j = 1, \dots, D$

where  $x_j^0, x_j^1$  and  $x_j^2$  are three given points in the  $j$  th-dimension;  $x_j^{\max}, x_j^{\text{mid}}$  and  $x_j^{\min}$  are the maximum, middle, and minimum fitness values among the three given points, respectively;  $\text{rand}$  is a random number uniformly distributed in the range (0, 1) and  $c_3$  and  $c_4$  are two real numbers in the range (0, 1); here,  $c_3 = 0.25$  and  $c_4 = 0.25$ .

When  $I = 0$ , i.e., at least two points are the same, the solution of  $x_j^3$  can be solved as the case of  $a = 0, b \neq 0$  using Eq. (c) in Eq. (12). Algorithm 2 shows the pseudocode of the Lagrange interpolation method.

#### 4. ADELI

Although DE is a simple and powerful evolutionary algorithm for many optimization problems [30], it still has problems of premature convergence and a slow convergence rate for solving some complex optimization problems [15]. As Lagrange interpolation can enhance an algorithm's exploitation capability and help accelerate convergence [23], it is introduced to DE by using a novel adaptive argument strategy. Moreover, in order to solve complex optimization problems, a self-adaptive method for the control parameters is introduced for the parameter settings in DE. The new version of DE includes three main elements: local search with Lagrange interpolation; self-adapting control parameter settings in DE; and adaptive argument strategy.

##### 4.1. Local search with Lagrange interpolation

The main aim of introducing LSLI is to enhance the exploitation capability of DE for local search at the neighbor of the individual with the best fitness ( $x^{\text{best}}$ ). As  $f(x^k) = f([x_1^k, x_2^k, \dots, x_D^k])$ , the fitness value of an individual is possibly influenced by all  $D$  parameters. The current best individual is discovered in the region nearby the global optimum. However, in some dimensions, a better fitness value may wait for further exploitation [26]. Hence, we implement LSLI for the local search in each dimension nearby the neighbor of the best individual to enhance the local search and convergence ability.

In each dimension of the search space, the initialization parameters of three temporary individuals  $x^1, x^2$ , and  $x^3$  are assigned by the best individual  $x^{\text{best}}$ . Then, we empirically develop Eqs. (13) and (14) to randomly reassign the parameters  $x_j^1$  and  $x_j^2$  of the two temporary individuals  $x^1$  and  $x^2$  in each dimension.

$$x_j^1 = x_j^{\text{best}} + R_j \quad (13)$$

$$x_j^2 = x_j^{\text{best}} - R_j \quad (14)$$

where  $x_j^{\text{best}}$  is the parameter of the best individual in the  $j$  th-dimension, and  $R_j$  is the search radius of  $x^{\text{best}}$  in the  $j$  th-dimension; it can be adaptively adjusted as Eq. (15) according to the distribution of the current population.

$$R_j = \frac{1}{N} (\max(X_j) - \min(X_j)) \text{rand}(0, 1) \quad (15)$$

where  $X_j$  are the parameters of the population in the  $j$  th-dimension,  $N$  is the size of the population, and  $\text{rand}(0, 1)$  is a uniformly distributed random number in the range (0, 1).

In the  $j$  th-dimensional search space, the parameters  $x_j^1$  and  $x_j^2$  are on the opposite sides of the best individual's current position  $x_j^{\text{best}}$ . The parameters  $x_j^{\text{best}}, x_j^1$  and  $x_j^2$ , treated as three points in the  $j$  th-dimensional search space, can perform Lagrange interpolation to obtain the parameter  $x_j^3$  of the individual  $x^3$  who may yield a better fitness value. If the fitness value  $f(x^1)$ ,  $f(x^2)$  or  $f(x^3)$  is better than  $f(x^{\text{best}})$ , then the information of the best individual  $x^{\text{best}}$  will be updated. In each dimension, LSLI consumes 3 FEs for calculating  $x^1, x^2$ , and  $x^3$ . Hence, it consumes  $3 * D$  FEs in total when LSLI is performed one time.

To provide a better understanding, the pseudocode of LSLI is presented in Algorithm 3.

##### 4.2. Self-adapting control parameters selection in DE

The performance of DE is significantly influenced by the control parameters, i.e., the scaling factor  $F$  and the crossover rate  $CR$  [30]. It is a difficult task to choose the suitable control parameters for optimizing increasingly complex real-world problems. In this paper, we introduce a simple and self-adaptive method, proposed by Brest et al. [3], to self-adaptively adjust the control parameters  $F$  and  $CR$ , which are given in Eqs. (16) and (17):

$$F_{i,G+1} = \begin{cases} F^{\text{low}} + \text{rand}(0, 1) * F^{\text{up}} & \text{rand}(0, 1) < \tau_1 \\ F_{i,G} & \text{otherwise} \end{cases} \quad (16)$$

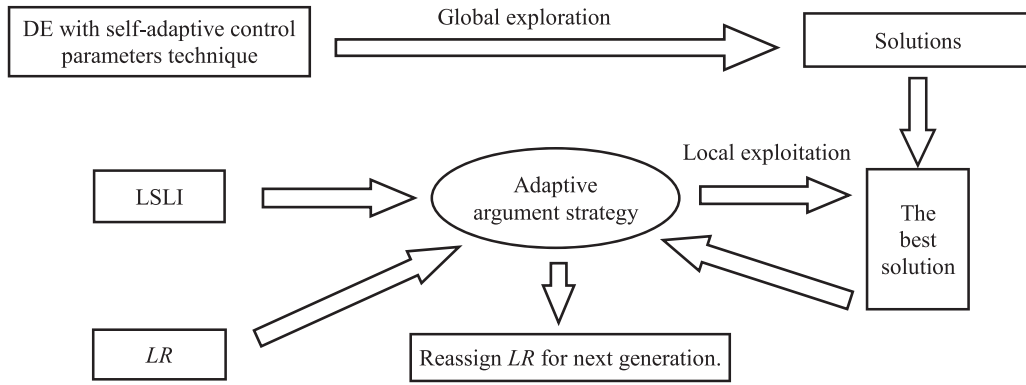

Fig. 2. The argument scheme of ADEL in one generation.

$$CR_{i,G+1} = \begin{cases} rand(0, 1) & rand(0, 1) < \tau_2 \\ CR_{i,G} & \text{otherwise} \end{cases} \quad (17)$$

where  $F^{low}$  and  $F^{up}$  are the minimum and maximum of the control parameter  $F$ , respectively.  $\tau_1$  and  $\tau_2$  are probabilities to adjust the control parameters  $F$  and  $CR$ , respectively.  $G$  is the index of the generation.

#### 4.3. Adaptive argument strategy

In ADEL, we insert LSLI into DE using an adaptive argument strategy, which is shown in Fig. 2. The main idea of ADEL is implemented in the following steps. First, DE with the self-adaptive control parameters method globally explores a problem's solution quickly in the entire search space. Then, the scheme decides whether to use LSLI according to the LSLI rate,  $LR$ , which is assigned by utilizing the feedback from the performance of LSLI in previous generation. Finally, the scheme adaptively determines whether to use LSLI for local exploitation near the best solution discovered by DE and to update  $LR$ .  $LR$  decides the probability of using LSLI in this generation. If the uniform random number is smaller than  $LR$ , LSLI will be implemented around the best individual; otherwise LSLI will not be implemented in this generation.

After LSLI and before the mutation procedure, if the offspring's fitness value  $f(x_{son}^{best})$  is better than the parent's best fitness value  $f(x_{best})$ , the offspring  $x_{son}^{best}$  will survive and perform the mutation operation, and  $LR$  will be adaptively reassigned with a larger value, which means a larger probability exists to use LSLI in the next generation; otherwise, the individual with the best fitness in the parents will remain and perform the mutation operation, and  $LR$  will be reassigned with a smaller value, which means a smaller probability exists to use LSLI the in next generation.  $LR$  is adaptively reassigned as Eq. (18).

$$LR_{G+1} = \begin{cases} \min(LR_G + 1, LR^{max}) & \text{if } (f(x_{son}^{best}) < f(x_{best})) \\ \max(LR_G - 1, LR^{min}) & \text{otherwise} \end{cases} \quad (18)$$

where  $f(x_{best})$  and  $f(x_{son}^{best})$  are the fitness values of the best parent and offspring individuals, respectively, when LSLI is implemented.  $LR^{min}$  and  $LR^{max}$  are two user-specified constants in the range  $[0, 1]$ , which control the minimum and maximum of  $LR$ , respectively.  $G$  is the index of the generation.

Note that ADEL only performs LSLI in the neighborhood of the best individual. Hence, the individuals should be ranked after the initialization and the selection procedures; then, the best individual should be memorized and updated in terms of the fitness value. The termination criteria for ADEL are  $FES$ . If LSLI is implemented in a generation, it would need  $3 \times D$  additional  $FES$ ; otherwise it needs  $N$   $FES$  in this generation. Algorithm 4 shows the pseudocode of ADEL.

## 5. Numerical experiments

### 5.1. Benchmark functions

In this experimentation, 30 benchmark functions in the CEC 2014 sets [25] are used to test the performance of the ADEL algorithm. The definitions of the CEC 2014 sets can be found in [25]. These 30 benchmark functions can be classified into four categories: unimodal functions ( $F_1$ – $F_3$ ), simple multimodal functions ( $F_4$ – $F_{16}$ ), hybrid functions ( $F_{17}$ – $F_{22}$ ), and composition functions ( $F_{23}$ – $F_{30}$ ). All benchmark functions are shifted to the shifted global optimum  $\mathbf{o}$ , which is randomly distributed in the range  $[-80, 80]^D$ , where  $\mathbf{o}_i = [o_{i1}, o_{i2}, \dots, o_{iD}]^T$ , and  $\mathbf{M}$  is the rotation matrix provided in [25]. The search ranges of all benchmarks are the same, within the range of  $[-100, 100]^D$ .

**Table 1**

Parameter settings of all involved algorithms.

No.	Algorithm	Year	Parameter setting	Reference
1.	ACOR	2008	$\xi=0.85$ (speed of convergence), $q=10^{-4}$ (locality of the search process), $k=50$ (archive size)	[36]
2.	QEA	2002	$\Delta\theta=0.01\pi$ (magnitude of rotation angle), migration period = 100	[21]
3.	aQIGA	2014	$P_c=0.5$ (crossover rate), $\sigma=1$ (standard deviation)	[5]
4.	CLPSO	2006	$w=0.9-0.4$ , $c_1=1.49445$ , $m_r=7$ (refreshing gap), $P_c=0.05+0.45[\exp(10(i-1)/(N-1)-1)]/(\exp(10)-1)$ (learning probability)	[26]
5.	jDE	2006	$CR=0.9$ , $F=0.5$ , $F^{\text{low}}=0.1$ , $F^{\text{up}}=0.9$ , $\tau_1=0.1$ , $\tau_2=0.1$	[3]

## 5.2. Experimental settings

To evaluate the efficiency of ADELI, ten evolutionary algorithms including ACOR [36], QEA [21], aQIGA [5], CLPSO [26], two DE versions, (jDE [3] and SaDE [30]), two TLBO versions (ETLBO [31] and DGSLBO [47]), and two BSA versions (BSA [8] and LBSA [7]) are evaluated to compare with the performance of ADELI.

For a fair comparison, all experiments are carried out on an Intel (R) i7 4850-HQ processor at 2.30 GHz with MATLAB R2016a. Each algorithm is independently implemented 30 times. In each experiment, the population size is set at 50 in the problems of 30 dimensions (30D) and 50 dimensions (50D). The termination criterion for all algorithms is the number of fitness evaluations (FEs); hence, the maximum FEs is set at 250,000. Note that for ACOR, QEA, aQIGA, CLPSO, and DE versions, the expenditure of FEs is  $N$  in one generation. For TLBO versions, the expenditure of FEs is  $2N$  in one generation. For ADELI, if a generation performed LSLI one time, it would need  $3D$  additional FEs in that generation, i.e.,  $(3D+N)$  FEs; otherwise, the generation would need  $N$  FEs. In this numerical experiment, the fitness value is the error between the optimal solution obtained by the algorithm and the real optimum.

The parameter settings of these algorithms are listed in Table 1, which are recommended in the original literature. Similar to most DE variants, ADELI requires setting the control parameters, i.e., the scaling factor ( $F$ ) and the crossover rate ( $CR$ ); however, it is difficult to choose suitable values. Hence, we use the same selection strategy as jDE [3]. The values of  $F^{\text{low}}$ ,  $F^{\text{up}}$ ,  $\tau_1$ , and  $\tau_2$  are the same as jDE and given in Table 1.

In addition,  $LR$  is an important parameter of ADELI that balances exploration and exploitation between DE and LSLI. Hence, an adaptive argument strategy is used to determine  $LR$  by  $LR^{\text{min}}$  and  $LR^{\text{max}}$ . If LSLI is unsuccessful,  $LR$  is set to  $LR^{\text{min}}$ , which means that LSLI cannot achieve a better solution than the best individual in this generation, and LSLI may not be suitable for this region. In this paper, we set  $LR^{\text{min}}$  with a small value of 0.1. Conversely,  $LR$  will be reassigned by using a large probability  $LR^{\text{max}}$  when LSLI obtains a better solution. In this study, we test four ADELIs with different  $LR^{\text{max}}$  {0.6, 0.7, 0.8, 0.9} and compare them with jDE. The mean error, mean time, and mean LSLI ratio obtained from 30 runs for the 30D functions in the CEC 2014 sets are shown in Table 2.

To observe the utilization rate of LSLI, we introduce the LSLI ratio, which is defined by

$$\text{LSLI ratio} = \frac{\text{FEs}^{\text{LSLI}}}{\text{Max FEs}} \quad (19)$$

where  $\text{MaxFEs}$  is the maximum FEs, and  $\text{FEs}^{\text{LSLI}}$  is the total expenditure of FEs of LSLI.

From the results in Table 2, we can observe that the adaptive argument mechanism of ADELI can work well by using different LSLI ratios on different problems. When  $LR^{\text{max}}$  is set to 0.9, ADELI performs the best, achieving the best mean error on 11 functions. In addition, all ADELIs spends less CPU time than jDE on most functions, and the higher  $LR^{\text{max}}$  it uses, the less time it takes. Considering two main factors, i.e., computational cost and solution accuracy, comprehensively, we set  $LR^{\text{max}}$  to 0.9 in our numerical experiments.

## 5.3. Comparison of the solution accuracy and efficiency

### 5.3.1. Results for the 30D problems

Table 3 shows the mean time of ADELI compared with the other ten algorithms for the 30D benchmark functions over 30 independent runs. We can observe that BSA, ADELI, LBSA, and jDE are the top four algorithms which spend the least time on most functions.

The mean, standard deviation and best solutions of eleven algorithms on thirty test functions with 30 dimensions (30D) are shown in Table 4. The best results among the eleven algorithms are shown in boldface. Moreover, the rank in terms of the mean for each function, and its average rank of eleven algorithms are presented in Table 4.

**Table 2**The mean error, mean time and mean LSLI ratio on thirty 30D test functions with different  $LR^{\max}$  (the boldface is the best mean error).

jDE				$LR^{\max} = 0.6$			$LR^{\max} = 0.7$			$LR^{\max} = 0.8$			$LR^{\max} = 0.9$

In Table 4, it can be observed that ADELI outperforms the other ten algorithms, with respect to the mean, on fourteen functions (F1, F2, F3, F4, F5, F8, F12, F13, F15, F17, F18, F19, F20, and F22). jDE surpasses other algorithms on five functions (F10, F23, F28, F29, and F30). SaDE is superior to other algorithms on four functions (F6, F7, F21, and F27). LBSA performs the best among all algorithms on three functions (F9, F11, and F14). For function F16, aQIGA and LBSA have the best performance, obtaining the minimum mean. For function F24, ETLBO, and DGSTLBO perform better than the other algorithms in terms of the mean. For function F25, jDE and ETLBO have the least mean. For function F26, CLPSO, jDE, SaDE, ETLBO, BSA, LBSA and ADELI outperform other algorithms with respect to the mean. ADELI ranks in the first place on fifteen functions, jDE on seven functions, and SaDE and LBSA on five functions. Additionally, the average rank of ADELI for 30D problems is 2.23, which is the best value among all competitor algorithms. Hence, it can be concluded that ADELI performs the best, and achieves good solution accuracy on 30-dimensional global optimization problems.

### 5.3.2. Results for the 50D problems

Table 5 presents the mean, standard deviation, best solution, rank of mean, and its average rank on thirty benchmark functions in 50 dimensions. The best results are shown in boldface. From Table 5, it can be observed that ADELI surpasses all other ten algorithms in terms of the mean on functions F1, F2, F3, F4, F13, F15, F17, F18, F19, F20, F21, and F22. ETLBO performs the best among all algorithms on functions F5, F12, and F27. LBSA outperforms other algorithms on functions F8, F11, and F14. jDE is superior to other algorithms on functions F6 and F7. SaDE performs better than the other algorithms on functions F9 and F10. ACOR performs the best with the smallest mean on functions F29 and F30. aQIGA surpasses other algorithms on function F16. For functions F23 and F28, ETLBO and DGSTLBO outperform other algorithms. For functions F24 and F25, ETLBO, and DGSTLBO obtain the least mean. For function F26, BSA and ADELI perform the best with respect to the mean. ADELI ranks in the first place on thirteen functions, ETLBO on seven functions, LBSA on four functions, DGSTLBO on three functions, jDE and SaDE on two functions, and BSA on one function. Additionally, the average rank of ADELI for 50D problems is 2.93, which is the best value among all competitor algorithms. Therefore, it can be concluded that ADELI performs the best, and achieves good solution accuracy on 50-dimensional global optimization problems.

Considering the average ranks of 30D functions and 50D functions, the top four methods are ADELI (2.58), LBSA (3.40), jDE (3.84), and SaDE (4.30). Hence, as indicated in Tables 3–5, ADELI shows the best overall performance among all algorithms on 30D and 50D problems, considering the mean of the error values.

Table 4

Comparative results of eleven algorithms on 30D test functions (the bold is the best solution).

#### 5.4. Comparison of the convergence performance

This section discusses the convergence characteristics of eleven algorithms on several 50D benchmark functions. Fig. 3 contains thirteen representative convergence graphs for functions F1, F2, and F3 (unimodal functions), F4, F13, and F15 (simple multimodal functions), F17, F18, F19, F20, F21, and F22 (hybrid functions), and F26 (composition function).

For F1, F2, F3, F4, F13, F15, F17, F19, F20, F21, and F22, ADEL1 converges faster than all other algorithms, and significantly improves the results on unimodal functions (F1, F2 and F3). For F18 and F26, the convergence curves of ADEL1 rapidly drop off at a relatively small position in the early stage of the optimization, and later it converges slowly, but eventually ADEL1 performs the best. As indicated in Fig. 3, ADEL1 achieves the fastest convergence speed and presents the best local search capability, which is superior to the other algorithms for these problems.

#### 5.5. Comparison of statistical tests

To make a thorough comparison, the *t* test, *F* test, and Duncan's post hoc test [2] were used to statistically analyze the difference between ADEL1 and the other algorithms.

Table 5

Comparative results of eleven algorithms on 50D test functions (the boldface is the best solution).

### 5.5.1. *t* test comparisons for 30D and 50D functions

The *t* test adopts a two-tailed test with a significance level of 0.05. Table 6 shows the *t* values and the *P* values on 30D functions between the ADEL and other algorithms. The better solutions between ADEL and other algorithms on thirty functions are shown in boldface. The symbols '+', '-', and '=' denote that ADEL performed significantly better than, significantly worse than, and almost the same as the algorithm under comparison, respectively. The average excellent and good rate, defined by  $\sum_{i=1}^{12} ((+)_i + (=)_i) / (30 \times 12)$  [7], between ADEL and the other algorithms on 30D functions is 95.56%. Table 7 presents *t* test results on 50D functions between the ADEL and other algorithms. The average excellent and good rate between ADEL and other algorithms on 50D functions is 90.28%. Hence, ADEL performs the best on both 30D and 50D functions, especially on 30D functions.

### 5.5.1. *F* test comparisons for 30D and 50D functions

In *F* test experiments, the hypothesis assumptions can be expressed as follows. H0: there is no difference among the algorithms; H1: there is at least one algorithm that has a different result from the other algorithms. There are eleven algorithms for thirty functions, which means the degree of freedom is ten, and the sample size is thirty. If we choose the significance level of 0.05, then the critical value is 2.4663, which can be found using the *F*-distribution table.

**Table 6**Comparison between ADEL1 and other algorithms using a *t*-test for 30D functions in the CEC 2014 sets.

Fig. 3. The convergence curves of the eleven algorithms on thirteen 50D benchmark functions.

After the calculation, the F-scores of the mean's ranks of 30D and 50D functions are 48.255 and 35.499, respectively, which are much higher than the critical value. Hence, the hypothesis  $H_0$  is rejected as these algorithms have unequal results.

### 5.5.2. Duncan's post hoc test comparisons for 30D and 50D functions

As the  $F$  test shows that there are significant differences between these algorithms, the Duncan's post hoc test is used to justify the difference between ADELI and the other algorithms. Table 8 shows the results of the significance between ADELI and the other algorithms, which are evaluated with SPSS software. It can be concluded that, ADELI significantly outperforms the other algorithms on 30D functions, except for jDE, SaDE, and LBSA, at a significance level of 0.05. For 50D problems, ADELI is significantly superior to the other algorithms, excluding jDE, SADE, ETLBO, and LBSA.

**Table 8**

Comparison between ADEL1 and other algorithms using the Duncan's post hoc test for 30D and 50D functions in the CEC 2014 sets.

Al.	ACOR	QEA	aQIGA	CLPSO	jDE	SaDE	ETLBO	DGSLBO	BSA	LBSA

**Fig. 4.** Variables of the four-bar mechanism used in this experiment.

Therefore, as indicated in Tables 6–8 and as noted from the results of the  $F$  tests, ADEL1 shows a statistically significant performance compared to all other algorithms on most of the problems with 30 dimensions and 50 dimensions.

## 6. Application example

This section considers the optimal synthesis problem of four-bar mechanisms utilizing the five algorithms presented in Section 5.2. The four-bar mechanism is a simple yet indispensable mechanism which has been widely used in various machines and devices. The dimensional synthesis of four-bar mechanisms is aimed at synthesizing a mechanism with minimum errors between the coupler points and target points to meet the design requirements.

### 6.1. Problem formulation

The schematic of the four-bar mechanism together with the variables is shown in Fig. 4. It consists of four links connected in a loop by four pivots, where point  $O_2$  and point  $O_4$  are two fixed pivots, and point  $A$  and point  $B$  are two moving pivots. Point  $C$  is the coupler point on the coupler link. The design variable vector,  $\mathbf{x}$ , is denoted by:

$$\mathbf{x} = [r_1, r_2, r_3, r_4, r_{cx}, r_{cy}, x_0, y_0, \theta_0, \theta_2^i], i = 1 \dots n. \quad (20)$$

where  $r_1, r_2, r_3$  and  $r_4$  are the length of the ground link, input link, coupler (floating link), and output link, respectively.  $r_{cx}$  and  $r_{cy}$  are the coordinates of the coupler point  $C$  in the relative coordinate system  $X_cY_c$ .  $x_0$  and  $y_0$  are the coordinates of joint  $O_2$  in the world coordinate system  $XOY$ .  $\theta_0$  is the angle of the stationary link with respect to the  $X$ -axis.  $\theta_2^i$  is the  $i$ th input angle corresponding to the  $i$ th desired point in the relative coordinate system  $X_cY_c$ .  $n$  is the number of target points.

The positions of coupler points corresponding to the set of input angles  $\{\theta_2^i\}$  in the world coordinate system  $XOY$  can be expressed as:

$$\{C^i(\mathbf{x})\} = \{C_x^i(\mathbf{x}), C_y^i(\mathbf{x})\}, i = 1 \dots n. \quad (21)$$

Angle  $\theta_3$  can be solved by the Freudenstein equation [16]. In the world coordinate system  $XOY$ , the  $i$ th position of the coupler point  $C$  for design variables  $\mathbf{x}$  can be written as:

$$\begin{cases} C_x^i(\mathbf{x}) = x_0 + r_2 \cos(\theta_2^i + \theta_0) + r_{cx} \cos(\theta_3^i + \theta_0) - r_{cy} \sin(\theta_3^i + \theta_0) \\ C_y^i(\mathbf{x}) = y_0 + r_2 \sin(\theta_2^i + \theta_0) + r_{cx} \sin(\theta_3^i + \theta_0) + r_{cy} \cos(\theta_3^i + \theta_0) \end{cases} \quad (22)$$

### 6.2. Constraints

This application considers two constraints as follows:

**Table 9**

The best fitness value, mean time and mean LSLI ratio for the synthesis problem of a four-bar mechanism with different  $LR^{\max}$ .

Func.	jDE	$LR^{\max} = 0.5$	$LR^{\max} = 0.6$	$LR^{\max} = 0.7$	$LR^{\max} = 0.8$	$LR^{\max} = 0.9$

22     end for  $i$ 
23      $FEs = FEs + N$ ;
24 end while

```

$FEs$ : the number of fitness evaluations.

### 6.2.1. Grashof condition

To make sure the shortest link can rotate a full  $360^\circ$  with respect to the neighboring link, the links' length of the four-bar linkage must satisfy the Grashof condition, which can be expressed by:

$$r_s + r_l \leq r_p + r_q \quad (23)$$

where  $r_s$  is the length of the shortest link,  $r_l$  is the length of the longest link, and  $r_p$  and  $r_q$  are the lengths of the remaining two links.

In addition, the input link should be a crank in this study, i.e., the input link is the shortest link:

$$r_2 = r_s \quad (24)$$

**Algorithm 2**

**6.2.2. Sequence condition**

To avoid the order defect, the sequence of input angles  $\{\theta_2^i\}$  should fulfil the clockwise (CW) or counterclockwise (CCW) rotation:

$$\text{CW} : \theta_2^k < \theta_2^{k-1} < \dots < \theta_2^2 < \theta_2^1 < \theta_2^n < \dots < \theta_2^{k+1} \quad (25)$$

$$\text{CCW} : \theta_2^k < \theta_2^{k+1} < \dots < \theta_2^n < \theta_2^1 < \theta_2^2 < \dots < \theta_2^{k-1} \quad (26)$$

where  $\theta_2^k = \min\{\theta_2^i\}, i = 1, \dots, n$ .

**6.3. Objective function**

This optimization problem is to minimize the error between the coupler points and target points. The target points should be reached by the coupler point on the synthesized four-bar mechanism, which can be given in the world coordinate

**Algorithm 4**

Pseudocode of ADELI.

system as follows:

$$\{C_d^i\} = \{C_{dx}^i, C_{dy}^i\}, i = 1 \dots n. \quad (27)$$

The objective function consists of two parts. The first part of objective function is the sum of the square of the Euclidean distances between the coupler points and the corresponding target points, which can be defined as:

$$f(x) = \sum_{i=1}^n \left[ (C_x^i(x) - C_{dx}^i)^2 + (C_y^i(x) - C_{dy}^i)^2 \right] \quad (28)$$

The second part of the objective function addresses the penalty functions. The Grashof condition and the sequence condition are introduced as the penalty functions. Finally, the objective function of the optimal problem can be expressed as:

Minimize:

$$f_{obj}(x) = \sum_{i=1}^n \left[ (C_x^i(x) - C_{dx}^i)^2 + (C_y^i(x) - C_{dy}^i)^2 \right] + h_1(x)M_1 + h_2(x)M_2 \quad (29)$$

Fig. 5. Convergence of the best values of the objective function of five algorithms.

Subject to:  $x_j \in [x_j^{\text{low}}, x_j^{\text{up}}], \forall x_j \in x, j = 1, \dots, D$  where  $h_1(x) = 1$  denotes that the Grashof condition is not satisfied, and  $h_1(x) = 0$  represents that the Grashof condition is satisfied.  $h_2(x) = 1$  denotes that the sequence condition is not satisfied, and  $h_2(x) = 0$  represents that the sequence condition is satisfied.  $M_1$  and  $M_2$  are the high values to penalize the objective function; here,  $M_1, M_2 = 10^4$ , and  $D$  is the number of variables to be optimized.  $x_j^{\text{low}}$  and  $x_j^{\text{up}}$  are the lower and upper boundaries of the  $j$ th design variables, respectively.

#### 6.4. Experimental settings for the synthesis problem

The mechanism synthesis problem is chosen from Cabrera [4]. This problem requires the couple point C to trace a trajectory along eighteen target points arranged in an irregular closed path with prescribed timing. Then, for this problem, the following are defined.

The design variables are:

$$x = [r_1, r_2, r_3, r_4, r_{cx}, r_{cy}, x_0, y_0, \theta_0, \theta_2^1].$$

The target points are:

$$\begin{aligned} \{C_d^i\} &= [(0.5, 1.1); (0.4, 1.1); (0.3, 1.1); (0.2, 1); (0.1, 0.9); (0.005, 0.75); (0.02, 0.6); (0, 0.5); (0, 0.4); \\ &(0.03, 0.3); (0.1, 0.25); (0.15, 0.2); (0.2, 0.3); (0.3, 0.4); (0.4, 0.5); (0.5, 0.7); (0.6, 0.9); (0.6, 1)], \\ \{\theta_2^i\} &= \{\theta_2^1 + (i - 1) \frac{\pi}{9}\}, i = 1, \dots, 18. \end{aligned}$$

The limits of the variables are:

$$r_1, r_2, r_3, r_4 \in [0, 50]; r_{cx}, r_{cy}, x_0, y_0 \in [-50, 50]; \theta_0, \theta_2^1 \in [0, 2\pi].$$

In this experiment, five algorithms, including CLPSO, jDE, ETLBO, LBSA, and ADELI, are implemented to synthesize a four-bar mechanism. Before the experiment of the synthesis of a four-bar mechanism, we conduct an experiment with five ADELIs with different  $LR^{\text{max}}$  from the set  $\{0.5, 0.6, 0.7, 0.8, 0.9\}$  and compare them with jDE. Considering the best fitness value, mean time, and mean LSLI ratio, the results over thirty independent runs for the four-bar synthesis problem are shown in Table 9. From the results in Table 9, we can observe that the adaptive argument mechanism of LSLI can work well by using different LSLI ratios. All five ADELIs obtain solutions with higher accuracy than jDE; moreover, when  $LR^{\text{max}} = 0.9$ , ADELI's solution is the most accurate. However, they require slightly more time than jDE. For the synthesis problem of a four-bar mechanism, the designer's most important goal is to ensure the solution accuracy. Hence, considering the solution accuracy, we set  $LR^{\text{max}}$  to 0.9 in the synthesis of the four-bar mechanism experiment. The maxFes is set to 10,000. The other parameter settings of the five algorithms are the same as those in Section 5.2.

## 6.5. Experimental results

The values of the best, the mean, and the standard deviations as well as the average convergence time and the standard deviations of the time achieved by the five algorithms for 30 runs are presented in Table 10. The best results are shown in boldface. According to the experimental results shown in Table 10, the best solution obtained by ADELi is the most accurate among the five algorithms. The mean and standard deviations obtained by LBSA are the best. The average convergence time and its standard deviations of CLPSO are the smallest.

The convergence graphs of the best values for this synthesis problem of the four-bar mechanism are shown in Fig. 5. It illustrates that the convergence speed of ADELi is the fastest, and the convergence accuracy of ADELi is the highest among the five constant algorithms.

For this mechanism synthesis problem, the main aim is to minimize the error between coupler points and target points. Hence, as indicated in Table 10 and Fig. 5, ADELi is superior to the other five algorithms with respect to the convergence speed and accuracy for this optima synthesis problem of four-bar mechanisms.

## 7. Conclusions

In this paper, a novel algorithm, called ADELi, has been presented as an extension of standard DE, which takes advantage of both DE and the Lagrange interpolation algorithm. In ADELi, a local search technique with Lagrange interpolation is applied to accelerate the convergence, and an adaptive argument strategy is proposed to perform LSLI near the best individual to discourage becoming trapped in local optima. Moreover, a self-adaptive method is introduced for controlling the parameter selection during the evolutionary process.

The performance of ADELi was tested on numerical benchmark functions in the CEC 2014 sets and compared to ten other EAs. The results show that ADELi with the adaptive local search technique is significantly better than the other ten EAs in most cases. For the application of mechanism synthesis, the optimization results also indicate that ADELi has the most accurate solution and the fastest convergence speed among the compared algorithms.

The proposed local search scheme with an adaptive argument strategy can be inserted into any other EAs to enhance their local exploitation capability. Future works will focus on extending ADELi's application domain to handle more practical optimization problems.
