(Received September 28, 1988; accepted in revised form May 30, 1989)

Summary

A study of the influence of the structure parameters of a silicon solar cell on both photocurrent and open-circuit voltage was performed. Fundamental carrier transport processes and non-ideal effects were taken into account with the main constraint relation that assumes a description of the current-voltage characteristic. The major influence of the recombination mechanism, compared with the band gap narrowing effect, on the cell performance was displayed. The work reveals practical doping levels to be $10^{17.5} \cdot 10^{18.5}$ cm⁻³ for the base and $10^{18} \cdot 10^{19.5}$ cm⁻³ for the emitter of an n⁺-p cell, from which other structure parameter values are not of crucial influence, in order to obtain high open-circuit voltage values together with high efficiency values, provided that the front surface of the cell is well passivated.

1. Introduction

High efficiency is the key to large-scale applicability of photovoltaic devices. In the last five years, basic research in the area of cell design, of material quality, of cell processing and modeling led to silicon cell efficiencies increasing from 14% to 22%.

In high performance actual silicon cells, the emitter region is made fairly thin $(0.1 - 0.2 \, \mu \text{m})$ of n⁺ type formed by low energy ion implantation, the emitter surface is oxide passivated to reduce surface recombination, and grid contact recombination is lowered by reducing the metal to silicon contact area [1-3]. The optical design has been improved [4] by forming microgrooves on the cell surface which allows oblique penetration of pho-

tons. Short-circuit current densities of these cells are very close to the theoretical limit but open-circuit voltage values are still less than the radiative limit.

In a solar cell, non-ideal effects, e.g. high level injection and energy gap shrinkage, influence the cell performance. Band edge distortion, present in heavily doped material, affects recombination, diffusion and drift. The band narrowing mechanism increases the steady state excess carrier density so the recombination currents are increased and the measured open-circuit voltage values are lower than expected. Crystal imperfections and foreign elements act as recombination centers producing low carrier lifetime values.

Major works in cell efficiency have placed the emphasis on improving the open-circuit voltage $V_{\rm oc}$ for maximum efficiency. Several different limits on the open-circuit voltage of silicon solar cells have been postulated from theoretical results by using approximated local equations or the first-order single diode model.

A systematic theory of the open-circuit voltage of a p-n junction has been given by Parrot [5] who has calculated $V_{\rm oc}$ as a function of the carrier concentrations at the junction. By assuming an abrupt p-n junction and non-degenerate conditions, he found that the photovoltage saturates when the illumination level increases to high levels. The effect of band gap narrowing in the heavily doped layers has been introduced [6] by using an effective intrinsic carrier concentration; $V_{\rm oc}$ saturation values are shown to be determined by the doping densities of the heavily doped layers. A general expression for the photovoltage valid for the case of a degenerate semiconductor has been considered [7] by using the Landsberg diffusion-mobility relation [8]. Later de Visschere [9] generalized Parrot's theory to include degenerate carrier densities and heavy doping effect. In these works, the open-circuit voltage values depend on the pn product values without relationship to the illumination level.

 $V_{\rm oc}$ has been related to internal potential differences [10] using an "effective" saturation current density $J_{\rm d}$ as a parameter. This method has been used [11-14] to describe the behavior of silicon solar cells in concentrated sunlight. A theory [15] based on the transport equation has been developed and applied to back-surface field (BSF) solar cells.

Weaver [16] performed exact numerical calculations (including band gap narrowing, Auger mechanism and non-uniform generation rate) to compare BSF solar cells with conventional cells.

Numerous published studies consider that $V_{\rm oc}$ may be expressed by the well known equation

$$V_{\rm oc} = (KT/q) \ln(I_{\rm ph}/I_0) + 1 \tag{1}$$

where $I_{\rm ph}$ is the photocurrent density and I_0 the dark reverse saturation current density. The solar cell is modeled with a constant current source $I_{\rm ph}$ in parallel with an ideal diode. The open-circuit voltage appears as a function of intrinsic parameters. Many results [17 - 21] have been obtained in this manner. This approach ignores the fact that eqn. (1) is not valid for discussing

the effect of recombination since it supposes an ideal diode with a quality factor which equals unity.

All these studies lead to theoretical values of $V_{\rm oc}$ less than the radiative limit or show limitations when optimizing structure parameters or when increasing the illumination level. Such results are attributed to recombination processes in the bulk of the cell or to the high surface recombination velocity of the metal-electrode interfaces, but this has not been shown by the theory. All the theories developed have assumed that the recombination current in the space-charge region is negligible and have considered a parameter, the surface recombination velocity, which is shown to take suitable values in order to explain desired results. So discrepancies between theory and experiment are attributed to approximations made in order to obtain manageable equations.

The analysis of solar cell performances must take into account non-ideal effects, e.g. high level injection, energy gap shrinkage, and recombination processes in the bulk, in the space-charge region and at the metal electrode interface, to obtain a description of the current-voltage characteristics. It is not correct to consider a structure with a cell design which has been optimized for operation in the open-circuit condition as giving the best efficiency. Experimental, theoretical and modeling studies of $V_{\rm oc}$ are interesting because they reveal information about fundamental mechanisms operating in the layers of the cells.

In this study of solar cell performances, fundamental processes (drift, diffusion, recombination, creation), non-ideal effects and cell design are taken into account in order to obtain a description of the current-voltage characteristics. The influences of physical mechanisms and of structure parameters on the photocurrent, the open-circuit voltage and the maximum output power are pointed out and optimum values are given.

2. Theory and discussion

Modeling studies [22 - 24] have shown that the current-voltage relation

$$f(I, V) = 0 (2)$$

with

$$f(I, V) = I_{\rm ph} - \sum_{i=1,2} I_{0i} \{ \exp(B_i V_{\rm d}) - 1 \} - V_{\rm d} / R_{\rm sh}$$
 (3)

where $V_d = V + IR_s$, $B_1 = q/KT$ and $B_2 = B_1/2$, is adequate to represent experimental data.

 I_{01} is the dark saturation current which results from electronic conduction phenomena in the quasi-neutral regions of the cell (diffusion, recombination, including the drift effect), and I_{02} is the excess current which may

result from a variety of causes. Recombination in the space-charge region and via deep levels [14, 25 - 27] or at a metal-semiconductor contact [28] are well known as causes of this behavior with a diode quality factor equal to 2. Current-proportional voltage is described by a lumped series resistance $R_{\rm s}$ and leakage currents are expressed by the addition of a lumped shunt resistance $R_{\rm sh}$.

The photocurrent $I_{\rm ph}$ depends on two kinds of factors: (1) factors associated with internal structural properties of the solar cell, such as the dopant concentrations $N_{\rm A}$ and $N_{\rm D}$, the surface recombination velocities $S_{\rm F}$ (front surface) and $S_{\rm B}$ (back surface), and the widths of the three parts, emitter (X), space charge (W) and base (H) regions of the cell; (2) the incident photon flux $F(\lambda)$ and absorption capacity of silicon $A(\lambda)$. Expressions of the contributions to the photocurrent from these three regions respectively $J_{\rm p}(\lambda)$, $J_{\rm n}(\lambda)$, $J_{\rm dr}(\lambda)$ as functions of parameters X, W, H, $S_{\rm F}$, $S_{\rm B}$, diffusion lengths $L_{\rm p}(L_{\rm n})$, diffusion coefficients $D_{\rm p}(D_{\rm n})$, and $A(\lambda)$, $F(\lambda)$ are given by eqns. (15), (19) and (20) of ref. 29. $I_{\rm ph}$ is obtained by integrating the expressions of monochromatic currents from $\lambda = 0.24~\mu{\rm m}$ to $\lambda = 1.08~\mu{\rm m}$ (useful bandwidth for silicon); the experimental values of $F(\lambda)$ and $A(\lambda)$ (AM 1 conditions) may be fitted with five linear curves (see Appendix 1). Some authors [21, 30, 31] used the generation rate of electron-hole pairs to calculate the observed short-circuit current as an approximation of $I_{\rm ph}$.

The reverse saturation current I_{01} (first diode in the model) is the classical diffusion-recombination current from the emitter and the base of the cell, taking into account the energy band gap narrowing [32] whose importance has been shown [17, 33].

The model of the solar cell adopted is that of an abrupt junction with homogeneously doped sides and it leads to the dark saturation current given by the following expression [29]

$$I_{01} = I_{0E} + I_{0B} \tag{4}$$

with

$$I_{0B} = q(n_i^2/N_A) (D_n/\tau_n)^{1/2} A/B$$
 (5)

$$I_{0E} = q(n_i^2/N_D)(D_p/\tau_p)^{1/2}C/D$$
 (6)

and

$$A = (S_{\rm F} L_{\rm p}/D_{\rm p}) \cosh(X/L_{\rm p}) + \sinh(X/L_{\rm p}) \tag{7}$$

$$B = (S_{\rm F} L_{\rm p}/D_{\rm p}) \sinh(X/L_{\rm p}) + \cosh(X/L_{\rm p})$$
(8)

$$C = (S_B L_n/D_n) \cosh(H/L_n) + \sinh(H/L_n)$$
(9)

$$D = (S_{\rm B}L_{\rm n}/D_{\rm n})\sinh(H/L_{\rm n}) + \cosh(H/L_{\rm n})$$
(10)

where the intrinsic carrier concentration n_i is replaced by the effective intrinsic concentration to take into account the energy band gap narrowing

[21, 32], and $\tau_{\rm n}$ ($\tau_{\rm p}$) is the electron (hole) lifetime in the base (emitter) region. Equation (4) gives $I_{0.1}$ as the sum of two terms, a base current $I_{0.B}$ and an emitter current $I_{0.E}$. Fossum et al. [17] have shown the emitter to be transparent to minority carriers when $S_{\rm F} \ll 10^2$ cm s⁻¹ and when the required transit time for minority carriers to cross the emitter is lower than the average minority carrier lifetime $\tau_{\rm p}$, which leads to the dominance of the base current in eqn. (4). Such results have been confirmed by Shibib and Fossum [18] who provided data taken on BSF silicon solar cells. $I_{0.2}$ is the total recombination current of electrons and holes including the space-charge region [26].

In this work, the doping concentrations $N_{\rm A}$ and $N_{\rm D}$ vary in their usual ranges for actual silicon solar cells, $10^{15}~10^{18.5}~{\rm cm}^{-3}$ for $N_{\rm A}$ and $10^{18}~10^{21}~{\rm cm}^{-3}$ for $N_{\rm D}$. So the Auger effect may be neglected in the base and has to be considered in the emitter; in these two cases, the lifetimes $\tau_{\rm n}$ and $\tau_{\rm p}$ and the diffusion coefficients are known [31] as functions of $N_{\rm A}$ and $N_{\rm D}$, and the diffusion length can be computed by the relations $L=(\tau D)^{1/2}$. In this way, the reverse saturation currents I_{0i} and the photocurrent $I_{\rm ph}$ are related to the structure parameters $N_{\rm A}$, $N_{\rm D}$, $N_{\rm D}$, $N_{\rm C}$, $N_{\rm C}$, $N_{\rm B}$. This model allows the description of cell performance with structure parameters taking into account the true value of the photocurrent when varying the cell structure or the illumination level.

The open-circuit voltage $V_{\rm oc}$, deduced from eqn. 3 by making I=0, is the solution of the implicit equation

$$I_{\rm ph} - V_{\rm oc}/R_{\rm sh} - \sum_{i=1,2} I_{0i} \{ \exp(B_i V_{\rm oc}) - 1 \} = 0$$
 (11)

The lumped shunt resistance value can be taken as equal to $1000 \Omega \text{ cm}^2$ [33] which is in good agreement with actual solar cells. For the maximum output power of Fig. 12, the series resistance R_s is taken equal to $0.1 \Omega \text{ cm}^2$ [33].

3. Results

3.1. Influence of intrinsic parameters on I_{ph}

Figures 1(a), (b) and (c) display the emitter, the space-charge and the base cumulative photocurrent values when increasing the absorbed photon wavelength. Photons with wavelength values less than 0.49 μ m are absorbed by the emitter and contribute to the emitter photocurrent. A great amount of those photons of wavelengths more than 0.49 μ m are absorbed by the two other regions and contribute to these two region photocurrents. The space-charge current shows a strong dependency on both the base doping level $N_{\rm A}$ and the emitter doping level $N_{\rm D}$.

3.2. Influence of structure parameters on $I_{\rm ph}$

To study the photocurrent $I_{\rm ph}$, the base width H and the back-surface recombination velocity $S_{\rm B}$ are taken to be greater than 80 $\mu {\rm m}$ and 10⁵ cm s⁻¹ respectively. A strong dependency of the total photocurrent on the

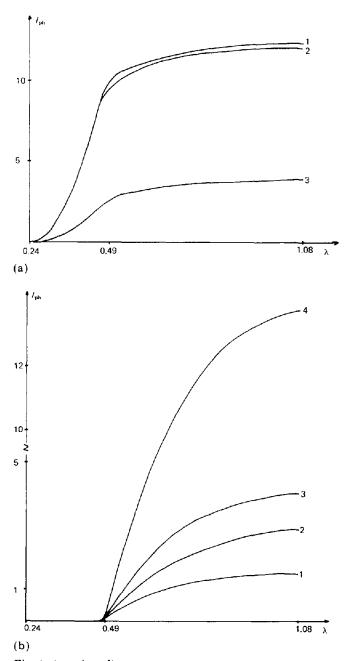

Fig. 1. (continued)

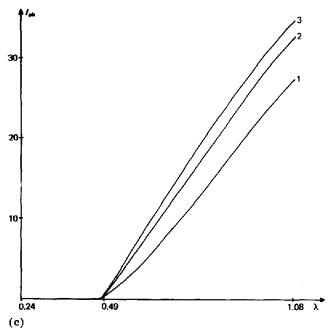

Fig. 1. (a) Cumulative emitter photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. photon wavelength λ (μ m) for $X=0.1~\mu$ m, $S_{\rm F}=100~{\rm cm~s^{-1}}$: for curves 1, 2 and 3, $N_{\rm D}$ is 10^{19} , 10^{20} and $10^{21}~{\rm cm^{-3}}$ respectively. (b) Cumulative space-charge photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. photon wavelength λ (μ m) for $X=0.1~\mu$ m, $S_{\rm F}=100~{\rm cm~s^{-1}}$: curve 1, $N_{\rm A}=10^{17}~{\rm cm^{-3}}$, $N_{\rm D}=10^{20}~{\rm cm^{-3}}$; curve 2, $N_{\rm A}=10^{16}~{\rm cm^{-3}}$, $N_{\rm D}=10^{20}~{\rm cm^{-3}}$; curve 3, $N_{\rm A}=10^{15}~{\rm cm^{-3}}$, $N_{\rm D}=10^{20}~{\rm cm^{-3}}$; curve 4, $N_{\rm A}=10^{16.5}~{\rm cm^{-3}}$, $N_{\rm D}=10^{17.5}~{\rm cm^{-3}}$. (c) Cumulative base photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. photon wavelength λ (μ m) for $N_{\rm D}=10^{20}~{\rm cm^{-3}}$, $X=0.1~\mu$ m, $H=295~\mu$ m, $S_{\rm F}=100~{\rm cm~s^{-1}}$, $S_{\rm B}=10^{15}~{\rm cm~s^{-1}}$: for curves 1, 2 and 3, $N_{\rm A}$ is 10^{15} , 10^{16} and $10^{17}~{\rm cm^{-3}}$ respectively.

emitter width appears on curves A, B and E in Fig. 2. It shows the generally postulated results concerning the need of a small emitter width for practical emitter and base doping levels and for front-surface recombination velocity $S_{\rm F}$ lower than 100 cm s⁻¹ in order to obtain high $I_{\rm ph}$ values. In the case of parameter $(N_{\rm A}, N_{\rm D}, S_{\rm F})$ values giving large $V_{\rm oc}$ values (see below), the total photocurrent does not depend on an emitter width lower than 1 μ m (Fig. 2, curve C) which is an important result for cell design.

We obtain no significant dependency of $I_{\rm ph}$ on the base width when H is greater than 80 $\mu{\rm m}$ and this result is in agreement with classical short-circuit current studies [29]. Figure 3 shows a strong dependency of the emitter photocurrent on the front-surface recombination velocity $S_{\rm F}$ as soon as $S_{\rm F}$ is strong enough to recombine the created electron-hole pairs before they can contribute to the photocurrent. For large $N_{\rm D}$ values, the influence of $S_{\rm F}$ is smaller but the photocurrent is considerably reduced. When the back-surface recombination velocity $S_{\rm B}$ is greater than 10^5 cm s⁻¹, $I_{\rm ph}$ does not depend on $S_{\rm B}$. A systematic representation of the emitter and base doping effects on the photocurrent are displayed in Figs. 4, 5, 6 and 7. The

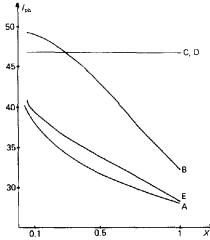

Fig. 2. Total photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. emitter width X (μ m): curves A and B, $N_{\rm A}=10^{16.5}$ cm⁻³, $N_{\rm D}=10^{20}$ cm⁻³, H=295 μ m, $S_{\rm B}=10^{15}$ cm s⁻¹; curve A, $S_{\rm F}=10^7$ cm s⁻¹; curve B, $S_{\rm F}=100$ cm s⁻¹; curve C, $N_{\rm A}=10^{17.7}$ cm⁻³, $N_{\rm D}=10^{18.8}$ cm⁻³, H=295 μ m, $S_{\rm F}=100$ cm s⁻¹, $S_{\rm B}=10^{15}$ cm s⁻¹; curve D, $N_{\rm A}$, $N_{\rm D}$, $S_{\rm B}$ as for curve C, H=100 μ m, $S_{\rm F}=0.01$ cm s⁻¹; curve E, $N_{\rm A}$, $N_{\rm D}$, H, $S_{\rm B}$ as for curve D, $S_{\rm F}=10^6$ cm s⁻¹.

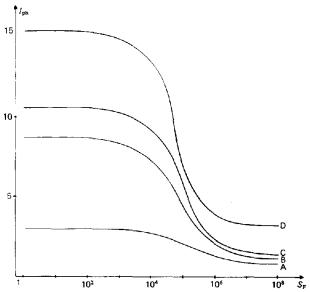

Fig. 3. Emitter photocurrent $I_{\rm ph}$ (mA cm⁻²) us. front-surface recombination velocity $S_{\rm F}$ (cm s⁻¹): for curves A, B and C, X = 0.1 μ m, $N_{\rm D}$ is 10^{21} , 10^{20} and 10^{19} cm⁻³ respectively; curve D, X = 0.3 μ m, $N_{\rm D}$ = $10^{18.9}$ cm⁻³.

emitter photocurrent strongly decreases when $N_{\rm D}$ increases beyond 10^{20} cm⁻³ and is nearly insensitive to $N_{\rm D}$ values less than 10^{20} cm⁻³. When the emitter is highly doped, the minority carrier lifetime strongly decreases because of the increase in the band-to-band Auger recombination. Figure 5

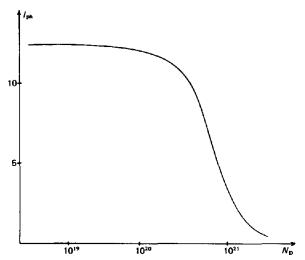

Fig. 4. Emitter photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. emitter doping $N_{\rm D}$ (cm⁻³): $X = 0.1~\mu{\rm m}$, $S_{\rm F} = 100~{\rm cm~s^{-1}}$.

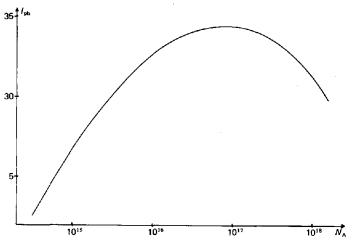

Fig. 5. Base photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. base doping $N_{\rm A}$ (cm⁻³): $N_{\rm D}$ = 10²⁰ cm⁻³, X = 0.1 μ m, H = 295 μ m, $S_{\rm F}$ = 100 cm s⁻¹, $S_{\rm B}$ = 10¹⁵ cm s⁻¹.

shows a maximum base photocurrent value for a base doping level around $N_{\rm A}=10^{17}~{\rm cm}^{-3}$, which corresponds to an equilibrium between the increase in created electron-hole pairs and their recombination as diffusion length is lowered by the increase in doping. Figures 6 and 7 conclude this study with the displays of the photocurrent vs. the doping levels, taking into account the space-charge contribution, and indicating useful doping values for obtaining large values of the total photocurrent.

3.3 Influence of structure parameters on $V_{\rm oc}$

The fundamental influence of the structure parameters on the opencircuit voltage has been previously placed in a prominent position and we

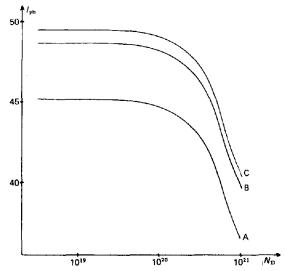

Fig. 6. Total photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. emitter doping $N_{\rm D}$ (cm⁻³), $X=0.1~\mu{\rm m}$, $H=295~\mu{\rm m}$, $S_{\rm F}=100~{\rm cm~s^{-1}}$, $S_{\rm B}=10^{15}~{\rm cm~s^{-1}}$: for curves A, B and C, $N_{\rm A}$ is 10^{18} , 10^{17} and $10^{16}~{\rm cm^{-3}}$ respectively.

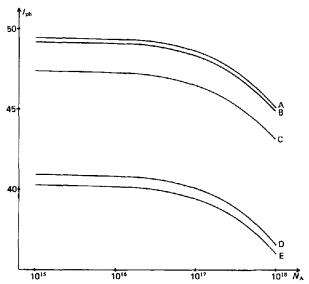

Fig. 7. Total photocurrent $I_{\rm ph}$ (mA cm⁻²) vs. base doping $N_{\rm A}$ (cm⁻³): for curves A–E, $N_{\rm D}$ is 10^{19} , 10^{20} , $10^{20.5}$, 10^{21} and 10^{19} cm⁻³ respectively, X = 0.1 μ m, H = 295 μ m, $S_{\rm B}$ = 10^{15} cm s⁻¹; curves A–D, $S_{\rm F}$ = 100 cm s⁻¹; curve E, $S_{\rm F}$ = 10^6 cm s⁻¹.

study first the dependence of $V_{\rm oc}$ on the emitter width X for the same $S_{\rm F}$ values as for $I_{\rm ph}$ (see Fig. 8). For small X values, lower than 0.3 μ m, $V_{\rm oc}$ is strongly dependent on $S_{\rm F}$; curves A and B in Fig. 8 compared with curves A and B in Fig. 2 illustrate that $V_{\rm oc}$ is limited by front-surface recombination. As X increases, $V_{\rm oc}$ becomes less sensitive to $S_{\rm F}$ and its decrease results

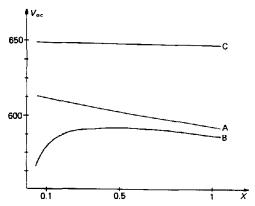

Fig. 8. Open-circuit voltage $V_{\rm oc}$ (mV) vs. emitter width X (μ m): curves A and C, $H=295~\mu$ m, $S_{\rm F}=100~{\rm cm~s^{-1}}$, $S_{\rm B}=10^5~{\rm cm~s^{-1}}$; curves A and B, $N_{\rm D}=10^{20}~{\rm cm^{-3}}$, $N_{\rm A}=10^{16.5}~{\rm cm^{-3}}$; curve B, $H=295~\mu$ m, $S_{\rm F}=10^7~{\rm cm~s^{-1}}$; curve C, $N_{\rm D}=10^{19}~{\rm cm^{-3}}$, $N_{\rm A}=10^{17.7}~{\rm cm^{-3}}$.

from the emitter photocurrent decrease, observed in Fig. 2. This is explained by the fact that the emitter width becomes larger than the diffusion length, (confirmed by curve C of Fig. 8) obtained for lower doping values (then higher diffusion lengths) chosen to lead to optimum $V_{\rm oc}$ values (see below). This constitutes an important result since curve C in Fig. 8 shows $V_{\rm oc}$ is insensitive to the emitter width (lower than $1~\mu m$) for some structure parameter values. Curve B in Fig. 9 shows that in the case of doping levels considered for optimum open-circuit voltage values, the front-surface recombination velocity influence on $V_{\rm oc}$ is stronger than for the case of larger doping values leading to reduced $V_{\rm oc}$ values. For low $S_{\rm F}$ values (less than $10^3~{\rm cm~s^{-1}}$) $V_{\rm oc}$ is insensitive to $S_{\rm F}$. This result is correlated to the previously discussed photocurrent curve Fig. 3; moreover, the diffusion current due to the emitter $I_{0\,\rm E}$ remains negligible compared with the base contribution $I_{0\,\rm B}$. This is no longer true when $S_{\rm F}$ increases beyond $10^3~{\rm cm~s^{-1}}$.

Such results display the comparative contributions to recombination from the surface effect and from the Auger effect which strongly increases

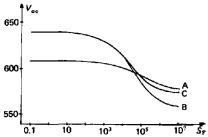

Fig. 9. Open-circuit voltage $V_{\rm oc}$ (mV) vs. front-surface velocity $S_{\rm F}$ (cm s⁻¹), $S_{\rm B}$ = 10^{15} cm s⁻¹: curve A, $N_{\rm D}$ = 10^{20} cm⁻³, $N_{\rm A}$ = $10^{16.5}$ cm⁻³, X = 0.1 μ m, H = 295 μ m; curve B, $N_{\rm D}$ = 10^{19} cm⁻³, $N_{\rm A}$ = $10^{17.7}$ cm⁻³, X = 0.1 μ m, H = 160 μ m; curve C, $N_{\rm D}$ = 10^{19} cm⁻³, $N_{\rm A}$ = $10^{17.7}$ cm⁻³, H = 160 μ m, X = 0.2 μ m.

with doping levels higher than 10¹⁹ cm⁻³. These are pointed out in Fig. 10 with the variations of calculated V_{oc} values vs. emitter doping level $N_{\rm D}$ for two different $S_{\rm F}$ values. $V_{\rm oc}$ is very dependent on $N_{\rm D}$ when $S_{\rm F}$ is high and is nearly constant when S_F is low. We have shown that these variations, previously observed [34 - 36], are a result of photocurrent behavior and put the stress on the importance of front-surface passivation. With an efficient passivation, a low emitter doping level around 10¹⁸ - 10^{19.5} cm⁻³ is enough to obtain large $V_{\rm oc}$ values. Figures 11 and 12 display the variations of $V_{\rm oc}$ against the base doping level for usual N_D values. The curves in Fig. 11 show that larger $V_{\rm oc}$ values are obtained in the base doping range $10^{17.5}$ - $10^{18.5}$ cm⁻³ regardless of the other parameters; the slight difference to the results in ref. 16 is due to the consideration of the space-charge contribution we used. These results may explain the flatter and the larger $V_{\alpha c}$ maximum value range in Fig. 11 compared with previous results [16]. The influence of band gap narrowing appears clearly in Fig. 12; $V_{\rm oc}$ is nearly saturating around $N_A = 10^{17}$ cm⁻³ and decreases beyond $N_A = 10^{18}$ cm⁻³.

In the case of $I_{\rm ph}$, no dependency of $V_{\rm oc}$ on the base width and the back-surface recombination velocity occurs provided that H and $S_{\rm B}$ are greater than 80 $\mu{\rm m}$ and 10^5 cm s⁻¹ respectively. Although not shown graphically, our model predicts higher values of the open-circuit voltage when relatively low values of the base width and the back-surface recombination velocity are assigned. For instance, we obtained $V_{\rm oc}$ = 690 mV with $N_{\rm D}$ = $10^{18.5}$ cm⁻³, $N_{\rm A}$ = 10^{17} cm⁻³, X = 0.2 $\mu{\rm m}$, H = 10 $\mu{\rm m}$, $S_{\rm F}$ = 1 cm s⁻¹ and $S_{\rm B}$ = 1 cm s⁻¹. In this structure, the minority carrier diffusion length in the base is greater than the base width which improves the collection of carriers.

Curve C of Fig. 12 illustrates an application of the model to the determination of the maximum output power $P_{\rm M}$; the existence of an optimum base doping level was known [21] and it is of importance to note that optimum $I_{\rm ph}$, $V_{\rm oc}$ and $P_{\rm M}$ values are obtained for different values of structure parameters.

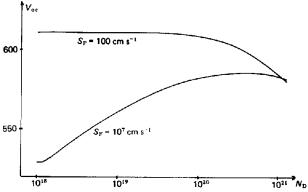

Fig. 10. Open-circuit voltage $V_{\rm oc}$ (mV) vs. emitter doping $N_{\rm D}$ (cm⁻³): $N_{\rm A} = 10^{16.5}$ cm⁻³, $X = 0.1 \, \mu$ m, $H = 295 \, \mu$ m, $S_{\rm B} = 10^{15}$ cm⁻³.

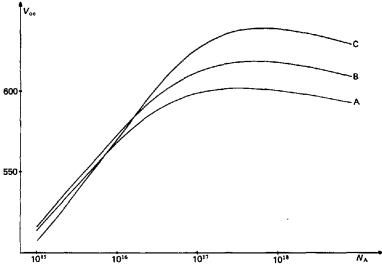

Fig. 11. Open-circuit voltage $V_{\rm oc}$ (mV) vs. base doping $N_{\rm A}$ (cm⁻³): curves A-C, H=295 $\mu{\rm m}$, $S_{\rm B}=10^{15}$ cm s⁻¹; curve A, $N_{\rm D}=10^{20}$ cm⁻³, X=0.2 $\mu{\rm m}$, $S_{\rm F}=10^6$ cm s⁻¹; curve B, $N_{\rm D}=10^{20}$ cm⁻³, X=0.6 $\mu{\rm m}$, $S_{\rm F}=100$ cm s⁻¹; curve C, $N_{\rm D}=10^{18.5}$ cm⁻³, X=0.05 $\mu{\rm m}$, $S_{\rm F}=2$ cm s⁻¹.

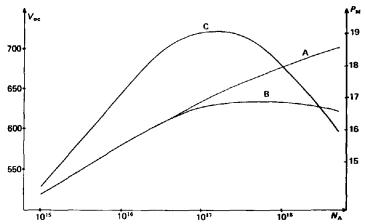

Fig. 12. Curves A and B, open-circuit voltage $V_{\rm oc}$ (mV) vs. base doping $N_{\rm A}$ (cm⁻³): curve A, with band gap narrowing; curve B, without band gap narrowing. Curve C, maximum output power $P_{\rm M}$ (mW cm⁻²) vs. $N_{\rm A}$ with band gap narrowing, $N_{\rm D}=10^{20}$ cm⁻³, X=0.1 $\mu{\rm m}$, $H=295~\mu{\rm m}$, $S_{\rm F}=100$ cm s⁻¹, $S_{\rm B}=10^{20}$ cm s⁻¹.

4. Conclusion

A systematic study of the influence of the structure parameters of a solar cell on both photocurrent and open-circuit voltage has been performed. Non-ideal effects and recombination processes have been taken into account by using a double-diode description of the current-voltage characteristics. In this way, actual cell structures are considered with constraint relations

between measurable characteristics. Our calculations reveal efficient doping level ranges, for the base $(10^{17.5} \cdot 10^{18.5} \text{ cm}^{-3})$ and for the emitter $(10^{18} \cdot 10^{19.5} \text{ cm}^{-3})$, where geometrical structure parameter values (emitter and base widths, back-surface recombination velocity) are not of crucial importance in obtaining high $V_{\rm oc}$ values. However, in the case of thin emitter region, the important lowering of $V_{\rm oc}$ values because of high front-surface recombination velocity is shown. The major influence on the cell performances of the recombination mechanism compared with the band gap narrowing effect has been displayed. It is also pointed out that large photocurrent, open-circuit voltage and maximum output power are not obtained for the same parameter values. This constitutes an important result and alters some preconceptions.

Appendix

The experimental curves given for $A(\lambda)$ and $F(\lambda)$ by Hovel [29] are valid in 100 Å bandwidths. In our model, they are fitted with five linear curves

$$0.24 \ \mu \text{m} \le \lambda \le 0.29 \ \mu \text{m}$$
 $A(\lambda) = -806\ 000/\lambda + 6590\ 000\ \text{cm}^{-1}$ (12)

$$0.30 \ \mu \text{m} \le \lambda \le 0.49 \ \mu \text{m}$$
 $A(\lambda) = 2614000/\lambda - 5244000 \ \text{cm}^{-1}$ (13)

$$0.50 \ \mu \text{m} \le \lambda \le 1.08 \ \mu \text{m}$$
 $A(\lambda) = 11658/\lambda - 10385 \ \text{cm}^{-1}$ (14)

and

0.24
$$\mu$$
m $\lambda \le 0.47 \mu$ m $F(\lambda) = (21.7\lambda - 5.21)10^{15}/\text{cm}^2 \text{ s}^{-1}$ (15)

$$0.48 \ \mu \text{m} \le \lambda \le 1.08 \ \mu \text{m}$$
 $F(\lambda) = (-2.74\lambda + 6.29)10^{15}/\text{cm}^2 \text{ s}^{-1}$ (16)

For every 100 Å bandwidth between 0.24 and 1.08 μ m, the photo-currents generated in each region of the cell $(J_{\rm n},J_{\rm dr},J_{\rm p})$ under AM 1 conditions are given by well known expressions [29] and the contributions $(I_{\rm n},I_{\rm dr},I_{\rm p})$ for all absorbed wavelengths are computed by using eqns. 12 - 16; for example

$$I_{\rm n} = \sum_{i=1 \text{ to } 85} J_{\rm n} \qquad \{\lambda = 0.24 + 0.01(i-1)\}$$
 (17)

and the total photocurrent is

$$I_{\rm ph} = I_{\rm n} + I_{\rm dr} + I_{\rm p} \tag{18}$$
